Abstract

`MVSIS` is a program modeled after `SIS`, but the logic network it works on is such that all variables can be multi-valued each with its own range. We include all the technology-independent transformations of `SIS` for combinational logic synthesis as well as transformations specific to multi-valued nodes such as `merge, pair_decode, encode, elim_part, print_part_value, print_range, reset_default`. `MVSIS` has been made to have the look and feel of `SIS`. `MVSIS` can read and write `BLIF-MV` files with the `read_blifmv` and `write_blifmv` commands, or read `BLIF` files with the `read_blif` command.

1 Introduction

Multi-level multi-valued (MV) logic synthesis can have many applications including:

1. Logic synthesis for multi-valued hardware devices.
2. Initial manipulation of a hardware description before it is encoded into binary and processed by standard binary logic synthesis programs; MV is a natural way to describe procedures at a higher level.
3. A front end to a software compiler, since software lends itself naturally to the evaluation of multi-valued variables in a single cycle. Strong logic synthesis transformations can be applied to compilers aimed at embedded applications.
4. Asynchronous synthesis

We have developed and included techniques for combinational optimization of MV networks. Like `SIS` [1, 2], `MVSIS` is an interactive tool, and has been made to have the look and feel of `SIS`[1]. When applied to purely binary networks, it behaves almost exactly like the technology independent part of `SIS`.

In the sequel, the main components of `MVSIS` are described, the input specification, the MV-transformations and special commands, verification by simulation, followed by a few examples illustrating the use of `MVSIS` in the design process.

[1] Currently we do not support registers. Inputs and outputs of registers can be treated as primary outputs and primary inputs respectively in a purely combinational network, but the current version of `MVSIS` does not include this capability. In addition, we do not support specification of external don't cares.

2 Design Specification

An MV circuit can be input to `MVSIS` as a netlist of MV-nodes (command: `read_blifmv`). We use a simple subset of `BLIF-MV` [3] used in `VIS` to specify the design. Such `BLIF-MV` files can be generated by the Verilog front-end to `VIS (vl2mv)` or be written out by `VIS`. Binary networks specified in `BLIF` (the format most commonly used in `SIS`) can also be read in (`read_blif`). After a design specification is read in, it is converted into an MV-network, a design representation used within `MVSIS`. An MV-network is a network of nodes; each node represents an MV-function with a single multi-valued output. The functions associated with each value (value-functions) of a node are stored in SOP form. There is one MV variable associated with the output of each node. An edge connects node i to node j if any of the value-functions at j depends explicitly on the variable associated with node i. The network has a set of primary inputs (all of which may be multi-valued) and a set of nodes, designated as the outputs of the network. An important distinction with other MV methods, is that in our representations, each variable can have a separate range of its own, including two values. All ranges are represented by the sets $\{0, 1, \ldots, n_i - 1\}$.

3 Combinational Optimization

3.1 Node Simplification

The logic value-functions (one for each output value) at an MV-node are simplified with the `simplify` command which uses the two-level logic minimizer ESPRESSO-MV. The objective of a general two-level logic minimizer is to find a logic representation with a minimum number of implicants (cubes) and literals while preserving functionality. Satisfiability don't cares from the local fanins and subset support variables are used in the minimization unless the `-d` option is used. After simplication, the value-functions are replaced with simplified versions if the new functions have been improved according to the cost function in use.

For each node, one of the value-functions is selected as the default value. For example, for a binary output function, the onset is usually the primary value and the offset, the default value. The default value-function is never looked at unless a command requires it. For example, if the output of a binary function is used in the complemented form in a fanout, and the node is eliminated, then the complement must be computed to effect the elimination. The values of the nodes and statistics of the network are based only on the non-default value-functions. However, there is one command `reset_default` which looks at each node and chooses a default value for it based on the cost of the node. For example, if the cost function is the number of cubes, `reset_default` will cause value functions to be minimized, and the default values will be chosen to be the values whose functions have the most cubes.

Currently, there are two cost functions which can be used. These can be selected using the `set` command. With `set cost 0`, the number of cubes in the functions is used. With `set cost 1`, the number of literals in the factored form is used. In the future, there will be more complex cost functions depending on the target of the application, possibly reflecting, the number of cubes, the number of nodes, the number of values, the number of fanins, etc..

The strongest kind of node simplification that can be performed on a network, is implemented using the `fullsimp` (alias `fs`) command. To perform this function on a multi-level MV-network, an appropriate don't care set is first generated. Subsets of the satisfiability and observability don't care sets (SDC and ODC respectively) are used. The notion of compatible observability don't cares (CODC) used in `SIS` has been generalized to take MV-nodes into account [4]. Given these, MV-image computation techniques

are used to map them to the local space of each node. An SDC of those nodes in the network whose support is a subset of the support of the node being simplified is also added to the local don't care set thus derived. This allows a form of Boolean substitution when `fs` is executed. Each node is then simplified by `ESPRESSO-MV` using this local don't care set.

During any of the above forms of simplification, if it is estimated that simplification will take too long, the node will be minimized with a simpler form of minimization or left unchanged. The complexity of an `ESPRESSO-MV` session is estimated by the number of cubes in the onset and don't care set, and the number of fanin variables. If this is too large, `ESPRESSO-MV` is not called. There is also a timeout for the `fullsimp` and `simplify` commands, controlled by the `-t` option. The specified time (in integer seconds) is shared among three time consuming computations; CODC computation, image computation, and `ESPRESSO-MV` minimization. If any one of these takes longer than the allocated time, the simplification for that node is terminated and only the local SDC is used for the node minimization. A default timeout value of 2 seconds is used.

3.2 Kernel and Cube Extraction

An important step in network optimization uses algebraic methods for extracting new nodes representing logic functions that are common factors of other nodes. Several techniques based on algebraic decomposition are part of `SIS`. Similarly, we have developed new algebraic techniques for MV-logic [5] which treat binary and multi-valued variables uniformly. They include methods for finding common sub-expressions, semi-algebraic division, decomposing a multi-valued network, and factoring a SOP form. The relevant commands and brief descriptions of their abilities are listed below.

1. The command `fx` looks at all the nodes in the network and tries to extract good common factors and create new nodes in the network, re-expressing other nodes in terms of these newly introduced nodes. It is one of the transforms used to break down large functions into smaller pieces. It has two options, -q and -g. The first generates candidate two-cube divisors by making each pair of cubes in a node value-function cube-free. These candidate two-cube divisors are made canonical and hashed into a table. A count is kept on the number of hits for each entry to obtain the value of a divisor. Complements are also kept if it is a two-cube expression. The divisor with the largest value is then extracted as a new node and substituted into all functions where applicable. For efficiency, the divisor table is only incrementally updated after each substitution.

   The `-g` option can generate additional divisors. This method extends `fx -q`. If no divisor is found by `fx -q`, `fx -g` first generates a set of candidate double cube divisors, one for each function, by factoring each node in the network. It then divides these candidate divisors, used in the factorization, into all other nodes and computes their values. The divisor with the largest value is extracted. In general, this method can find divisors that `fx -q` cannot find, since factoring can sometimes find divisors that cannot be obtained by the other method. This method can take longer CPU times if the number of cubes in the nodes is large.

2. The command `decomp` does a complete factoring of each node, but instead of creating a factored form for each, decomposes the node according to its factorization. Thus more intermediate nodes are produced this way. Such intermediates may not have been produced by `gx1` or `fx1`, so there is a possibility of finding better factors. After this, `resub` (see below) followed by `sweep` should be executed to eliminate duplicate factors. Then elimination can be done to clean up the network, possibly followed by `simplify` to look for Boolean substitutions.

3. Algebraic substitution of one node into another is performed in `MVSIS` using `resub [-d] [node-list]`. As an argument it takes a list of nodes that are to be algebraically substituted into all other nodes. If no list is given, all nodes are tried. All value-functions of the divisor are tried; the default value-function is also tried unless the `-d` option is given. We do not attempt to divide into the default function of other nodes, since their value-functions can be obtained by complementation. `resub` uses the new methods of "exact" semi-algebraic division, developed for multi-valued logic. There are two modes for this. If the divisor is a two-cube divisor, then a fast method based on matching is used; otherwise, a slower branch and bound method is used (called the satisfiability-matrix method). Although in theory all pairs of nodes must be looked at during `resub`, there are very effective filters to quickly determine if no algebraic substitution is possible.

3.3 Network Manipulations

1. The command `collapse` collapses nodes in the network. If no arguments are given, this collapses the entire multi-level network so the SOP forms for each output are in terms of the primary inputs only. Thus the number of nodes in the network will be exactly the number of primary outputs. If a single node name is given as an argument, that node will be collapsed. If two names are given, one must be a fanin of the other, in which case, the fanin node is collapsed into the fanout node. The collapsed node is removed from the network, if there is no other fanout.

2. The command `eliminate` eliminates all the nodes in the network whose value (as measured by the current setting for the cost function) does not exceed a specified threshold. The value of a node represents the total cost of the network with the node eliminated, minus the current cost of the network. If the value is not greater than the specified threshold, the node will be eliminated by collapsing the node into each of its fanouts. Of course, a primary input or a primary output will not be eliminated. The command iterates, since eliminating one node may affect the value of other nodes. The iteration continues until all remaining nodes have a value greater than the threshhold. However, if it is estimated that the elimination of a particular node will cause a blow-up in the number of cubes, the node will be kept (see `el_limit`).

3. `merge` is a command unique to `MVSIS`. It takes a list of nodes and forces a merge of them into a single multi-valued node. In the worst case, if for example, there are k binary nodes in the list, it will create a single node with 2^k values. However, some new value-functions may be 0, in which case they are not created. In addition, if a pair of values always appears together in all the fanouts, then their functions will be merged into a single value-function. If no list is given, merge looks for a likely list of candidates and merges them if it can achieve a gain in the value for the network. This may result in several additional multi-valued nodes through multiple merges. In case `merge` is given a list, the nodes will be merged regardless of the gain, provided the merging does not introduce cycles. Cycles will happen if there is a path from some node A to some node B in the list, which passes through a node not in the list.

4. `encode` is like the inverse of merge. It tries to find a good binary encoding for each multi-valued variable in the network, including primary inputs and outputs. At the end, each signal is encoded as a binary signal, including primary inputs and outputs. Then a binary file can be written (but currently only as a `blif-mv file`). An option (`-i`) puts encoders and decoders at the input and outputs, and converts the network to its original multi-valued inputs and outputs. The internal signals are binary

and the network between the encoders and decoders is exactly the same as if the `-i` option was not used. This encoded circuit can be validated against the original file. A good operational rule is to first encode a file with the `-i` option, validate the circuit, and then call `encode` to create the binary file. `encode` without the `-i` option will simply strip off the front-end and back-end encoders and decoders.

The encoding heuristic starts from the outputs and in reverse topological order works backwards towards the primary inputs. At each node, its output is encoded using the information on how its fanouts are used.

5. `pair_decode` does bit pairing to create new multi-valued nodes. It looks for a "best" pair of signals to pair together. Then it creates a new node (if its value is greater than the threshold) with value-functions equal to all the decodes of the pair. For example, if both signals are binary, then a 4-valued node is created and algebraically substituted into nodes which depend on at least one of these decodes. Finally, any set of values of the new node, which always appear together in the fanouts, are merged into a single value of the new node. After this step, `simplify` should be executed to effect full substitution. A threshold controls when a new pair is acceptable in terms of its estimated effect on the cost of the network.

6. `eliminate_part` is a command like eliminate, except it works only on multi-valued output nodes and can eliminate some of the value-parts for the nodes. A specified threshold controls which parts are to be eliminated. The values given to each of the parts is heuristic and each part is ordered using this value. To see the accumulated value of the parts, the command `print_part_value` shows the ordering of the parts, and the accumulated values from least to greatest. For example, for a particular node `m` it might print out the following,

   $$m:\ (110)\ 12\ 30\ 50\ 68\ 88\ 112\ 136\ 160\ 184\ (6\ 3\ 0\ 7\ 8\ 5\ 2\ 1\ 4\ )$$

   The name `m` is first followed by the normal value of the node (110), then a vector of the accumulated part values $12, 30, \ldots$, where 12 is the value of the 6^{th} part, 30 is 12 plus the value of the 3^{rd} part, etc. If the command `eliminate_part 30` is given, `MVSIS` will eliminate the first two values in the order by merging their functions, and then selecting a new default value for the new function. The merged part may have a larger function so it would replace the previous default part.

7. `undo` replaces the current network with the previous one. This is particularly useful if a forced merge results in a worse network. The combination `merge` and `undo` allows one to experiment with different mergings.Like `SIS`, `undo` treats `fs` special so that one is able to do two commands like `merge; fs` and `undo` will revert back to the circuit before the `merge`.

3.4 IterationTimeouts and Filters

Several commands have the option to apply the command a given number `n` times, or until no change occurs in the network. These commands are `eliminate, pair_decode, gx, fx` and `fullsimp`. The command structure is, for example `eliminate -i n <threshold>` where `n` is the iteration count. If no `-i` option is given, iteration to a fixed point is implied.

Many commands have a timeout option `-t`. For example, `pair_decode -t 1 10` will cause a timeout after 1 second has been used for finding a best pair. When it times out, it selects the best pair seen so far and if its value is greater than 10 will cause a new node to be produced. Commands with the `-t n` option

are `fullsimp, simplify, pair_decode, collapse, fx`. Other commands have internal timeouts while `print_factor` and `decomp` have a timeout controlled by `time_limit` a global parameter that can be set by the `set` command.

Several commands have filters, so that if the number of cubes in a cover exceeds a threshold, the operation is skipped on that node. These commands include `reset_default, fx` and `merge`.

3.5 Printing, reading and writing

There is one write command, `write_blifmv`, and two read commands, `read_blifmv` and `read_blif`. The latter reads in ordinary `BLIF` files. Currently, `MVSIS` is not able to read in `BLIF` files with registers.

To view the results at any stage, there are several print commands which print to the console. `print` prints the SOP form of each value (including the default value if the option `-d` is given) of each node in the network. `print_factor` prints the factored form of each value-function (excluding the default) of each node in the network. Each of these can take, as argument, a list of names of nodes to be printed. In general, *, like `SIS`, stands for all a list of nodes in the network.

`print_range` prints out the size of the range for each variable; `print_value` the value of each node (according to the current cost function; `print_stats` the statistics of the network in terms of the network name, the number of primary outputs, the number of nodes, the number of cubes, and the number of literals in the cubes. `print_stats -f` also prints out the number of literals in the factored forms of the non-default value-functions. `print_io` prints the inputs and outputs of the network. If a list of nodes is given, it prints out the fanins and fanouts of each node in the list.

Sometimes, in order to view an output or factorization better, it is useful to change the names of the variables to short names using the command `chng_name`. It is a toggle between short names and the original names. Associated is a command `reset_names` which resets the naming of short names for the variables so that all variables appear in lexigraphic order with no gaps in the naming. Thus inputs are named first, $\{a, b, c, \ldots\}$, then outputs, and finally intermediate nodes.

3.6 Setting global parameters

The `set` command sets various global parameters, which control the transformations. With no argument, `set` prints out the current values of the global parameters.

1. `cost` controls the type of cost function to be used in the evaluation of the value of a node. `set cost 0` uses the number of cubes as the cost function; `set cost 1` uses the number of literals in the factored form.

2. `time_limit`, controls the maximum amount of time (in seconds) that can be spent in factoring a single function or in decomposing a function during `decomp`. Since MV-algebraic factoring may take some time, this is useful in controlling the time spent in the factoring process, especially when the factoring is only being used to estimate the value of a node or to produce a readable output.

3. `el_limit` controls when a node will be eliminated. It may be that eliminating a node can result in a fanout becoming too large. For each fanout, we estimate the number of cubes that will result after elimination. If this estimate exceeds the maximum of `el_limit` and twice the largest cover of any node value, then the elimination is aborted. A similar control is in `SIS`.

4. `autoexec` can be given a command which will automatically execute after each command line is executed. A typical use is `set autoexec print_stats -f`, which will print out the statistics (including literals in the factored forms) of the network after each transformation.

5. `alias` is like `set`. It is used to create nick-names for various commands. For example `alias pfs print_stats -f` can be used to print out the stats of the network (including the number of literals in the factored forms) with the single command `pfs`. `alias` with no arguments will print out a list of all aliases defined so far. A typical set of aliases is incorporated in the file `.mvsisrc`, which is executed when `MVSIS` is started.

3.7 Other commands

1. `source` reads and executes commands from a file (`script` file).

2. `sweep` successively eliminates single input intermediate nodes in the network and deletes nodes with no fanouts.

3. `help` prints the set of commands available and with a single argument, a command, will print a detailed description of the command.

4 Verification

MV-networks can be verified in `MVSIS` by simulation. The command `validate` verifies the combinational equivalence of two networks by simulating the networks on random vectors, and comparing the outputs. The number of random vectors can be provided by the user from the command line. Command `gen_vec` generates a specified number of random input vectors appropriate for the ranges of the primary inputs, and writes them into a file. This can be used by the command `simulate`, which simulates the network and produces the results at the primary outputs. If a formal MDD-based verification is desired, one can write out `BLIF-MV` files, read it into `VIS`, and use its command `comb_verify`.

5 Examples Session

We illustrate `MVSIS` with two examples. The specification of each example is given in the `BLIF-MV` format (see `BLIF-MV` documentation in `VIS`).

.end
```

The above example is stored in a file called `matmul-c`. We start `MVSIS` with the command `mvsis`. Using the `.mvsisrc` file, the cost function is set to 1, i.e. cost is the number of literals in the factored forms and we change to the short names mode. The following aliases are used:

```
rl               read_blifmv
saf              set autoexec print_stats -f
fs  fullsimp
rsd              reset_default
pr               print_range
s                simplify -t 2
pf               print_factor
m                merge
pr               print_range
pio              print_io
el               eliminate
rsn              reset_name
pd              pair_decode

mvsis> vl aluack.mv
Networks are combinationally equivalent according to simulation.
```

Note that in the above example, after `enm`, several operations were performed on the circuit like `fs`. Even though all the internal nodes are binary valued, since the primary inputs are still multi-valued, some SOP forms are binary output multi-valued input, so the final circuit is not truly binary. To get a truly binary circuit, the command `encode` should be used. Then further network manipulations can be done without causing a multi-valued circuit (as long as `merge` and `pair_decode` are not called). For example, `source master.scriptb` can be executed to further simplify the network without creating any multi-valued nodes.

6 Two Scripts and Aliases

We provide two scripts for simplifying networks, `master.script` and `master.scriptb`. The second is the same as the first except for calling `pair_decode`. It is to be used after `encode` has been used to encode the network into purely a binary network. It will not produce any intermediate nodes with more than two values. The listing for `master.script` is given below. Also a set of aliases included in the `.mvsisrc` file is shown.

7 Caveats

1. `MVSIS` only works correctly on deterministic networks, i.e. ones where any primary output as a function of the primary inputs, has at most one value per minterm. We do not check for non-determinism. If a network is non-deterministic, it can result in a new network that is not equivalent to the original. If a node is incompletely specified, unspecified minterms are assigned to the default value when the circuit is read in. Incomplete specification will not result in a circuit not verifying against its original.

2. `MVSIS` can be applied to binary files by using the `read_blif` command. The results can be compared to those obtained by `SIS`. At this time we are still tuning the algorithms in `MVSIS` and comparing with `SIS` on binary files. `SIS` has a set of filters which are used to estimate when a result may blow up and if so it will not do the computation. We are still experimenting with similar filters in `MVSIS`. Nevertheless, `MVSIS` is pretty competitive with `SIS` in terms of speed and results.

3. As mentioned, formal verification can be done by writing a file and using `VIS`. For now, we have not built in a formal verification method, like `SIS` which can compute BDDs for two networks and compare them. Our verification is only by simulation through the `validate` command.

4. `MVSIS` is being made available only as an executable running under LINUX. This saves us a lot of development effort that would be expended in releasing source code which is compilable on various

machines running under different environments. Perhaps in the future, source code can be released so that users can experiment with adding different algorithms, as SIS by many people. It is easy to port the code to `alphas` and `SUNs`. If there are users who desire `MVSIS` source code, we may work with individuals to make it available under special requests.

5. `MVSIS` does not handle designs with registers yet. If a user wants to experiment with such designs s/he can edit a `BLIF` or `BLIF-MV` file, remove the latches, make latch inputs outputs and latch outputs inputs. Then purely combinational optimization can be done on the modified design. In the future, we should have the ability to handle sequential designs. A `BLIF-MV` file can be generated using `vl2mv` which translates `verilog` to `BLIF-MV`. `vl2mv` is available as part of `VIS`. However, in general, the `BLIF-MV` files so generated may contain latches and hence need to be modified.

6. We do not handle external don't care specification. `SIS` does this by allowing for the specification of a don't care network. Eventually we will have this capability. If a node in the network is incompletely specified, the missing minterms will be assigned to the current default value for that node.

Acknowledgements

We gratefully acknowledge the support of the SRC in funding this project under contract 683.004. In addition, the logic synthesis class of Spring 1999 at Berkeley started `MVSIS` as a combined class project under the guidance of Subarna Sinha, class TA. The class members were Yunjian Jiang, Niraj Shah, Scott Weber, Heloise Hse, Fernando DiBenederos, David Chinnery, and Rupak Majumdar.
